We present first-principles results for Sc-doped ZnO thin films. Neighboring Sc atoms in the surface and/or subsurface layers are found to be coupled ferromagnetically, where only two of the possible configurations induce spin polarization. In the first configuration, the polarization is carried by the Sc d states as expected for transition metal doping. However, there is a second configuration which is energetically favorable. It is governed by polarized hybrid states of the Zn s, O p, and Sc d orbitals. Such highly delocalized states can be an important ingredient for understanding the magnetism of doped ZnO thin films. c) 2012 American Institute of Physics.

The manipulation of the electronic spin for information processing gives rise to many new applications. However, the field of spintronics is in need of semiconducting ferromagnetic materials at room temperature. Nowadays, it is possible to achieve both properties in a single material by doping of magnetic impurities (e.g., V, Cr, Mn, Fe, Co or Ni) into a semiconducting host (e.g., ZnO, TiO2, GaN), what is most commonly known as a dilute magnetic semiconductor (DMS) or dilute magnetic oxide (DMO). Of all DMOs, ZnO (owing to the wide band gap of 3.3 eV and large exciton binding energy of 60 meV) is a potential host material for high Curie temperature ferromagnetism under doping with 3d transition metal ions. Following the prediction of Dietl et al.,5 that ZnO should have a high Curie temperature for hole doping, there have been various experimental reports proving or disproving a high Curie temperature ferromagnetism in this system. Theoretically, most of the materials that have been studied are semiconductors doped with transition metals. Because of the strong coupling between 3d states of the magnetic ions and the host p states, DMOs have been predicted and, in some cases, observed to show hole-mediated ferromagnetism above room temperatures. However, there is still a debate on whether the magnetic behavior of DMOs is an intrinsic property or due to nanoclusters of a magnetic phase or both.

A way to avoid problems with magnetic precipitates is to dope semiconductors or oxides with nonmagnetic elements instead of magnetic transition metals. Following this idea, room temperature ferromagnetism has been demonstrated in Cu and Ti-doped ZnO.9–12 Surprisingly, it has been observed that a (110) oriented thin film of ZnO with Sc impurities also shows ferromagnetism at room temperature13 with a Sc magnetic moment of 0.3 μB. It has been claimed that the fabrication of DMOs with nonmagnetic dopants is more challenging. On the theoretical side, there have been few reports on Sc-doped ZnO. Previous ab-initio calculations14 on bulk Sc-doped ZnO found no magnetic order, in contrast to the experiment, which calls for an explanation. In contrast to the bulk, the broken periodicity at a surface leads to modifications of the chemical bonding. This particularly affects the orbitals which are no longer involved in bonding. Their energies will shift and they will consequently be populated more or less than in the bulk. If orbitals become partially occupied (ideally half filled), they may favor spin polarization.

In order to provide fundamental insight into the interaction of Sc with a ZnO host and how the interaction can induce magnetism, we explore in the present work the electronic and magnetic properties of Sc-doped ZnO thin films by first principles calculations. Note that nonmagnetic Sc can induce a ferromagnetic ordering in an oxide host due to unfilled 3d states.

All our calculations are carried out within the framework of the spin-density functional theory using the projected augmented wave (PAW) method as implemented in the Vienna Ab initio Simulation Package. A plane wave basis set and PAW potentials with the valence states 3d10 and 4s2 for Zn, 2s2 and 2p6 for O, and 3p6, 4s2, and 3d4 for Sc are employed. An energy cut-off of 520 eV for the plane-wave expansion of the PAWs is used. The exchange-correlation interaction is treated in the generalized gradient approximation (GGA) using the parametrization of Perdew, Burke, and Ernzerhof. Moreover, we have applied the rotationally invariant version of the GGA+U method introduced by Liechtenstein et al. The on-site Coulomb interaction, U, and on-site exchange interaction, J, are applied to the d orbitals of Zn and Sc (7 eV and 1 eV, respectively). Geometry optimization is performed by conjugate-gradient minimization of the Hellmann-Feynman forces on the atoms and the stresses in the unit cell. Atomic coordinates and axial ratios have been relaxed for different volumes of the unit cell. Convergence is assumed for an energy difference between two successive iterations less than 10−6 eV per unit cell and forces on the atoms less than 0.01 eV/Å. All Brillouin zone integrations are performed with a Monkhorst-Pack mesh. Meshes of 6 × 4 × 1 and 8 × 6 × 2 points are found to be sufficient for the geometry optimization and electronic structure calculations, respectively.

In order to provide fundamental insight into the interaction of Sc with a ZnO host and how the interaction can induce magnetism, we explore in the present work the electronic and magnetic properties of Sc-doped ZnO thin films by first principles calculations. Note that nonmagnetic Sc can induce a ferromagnetic ordering in an oxide host due to unfilled 3d states.

All our calculations are carried out within the framework of the spin-density functional theory using the projected augmented wave (PAW) method as implemented in the Vienna Ab initio Simulation Package. A plane wave basis set and PAW potentials with the valence states 3d10 and 4s2 for Zn, 2s2 and 2p6 for O, and 3p6, 4s2, and 3d4 for Sc are employed. An energy cut-off of 520 eV for the plane-wave expansion of the PAWs is used. The exchange-correlation interaction is treated in the generalized gradient approximation (GGA) using the parametrization of Perdew, Burke, and Ernzerhof. Moreover, we have applied the rotationally invariant version of the GGA+U method introduced by Liechtenstein et al. The on-site Coulomb interaction, U, and on-site exchange interaction, J, are applied to the d orbitals of Zn and Sc (7 eV and 1 eV, respectively). Geometry optimization is performed by conjugate-gradient minimization of the Hellmann-Feynman forces on the atoms and the stresses in the unit cell. Atomic coordinates and axial ratios have been relaxed for different volumes of the unit cell. Convergence is assumed for an energy difference between two successive iterations less than 10−6 eV per unit cell and forces on the atoms less than 0.01 eV/Å. All Brillouin zone integrations are performed with a Monkhorst-Pack mesh. Meshes of 6 × 4 × 1 and 8 × 6 × 2 points are found to be sufficient for the geometry optimization and electronic structure calculations, respectively.
We construct the ZnO thin film from the optimized wurtzite bulk ZnO structure with lattice parameters $a = 3.29\ \text{Å}$ and $c = 5.30\ \text{Å}$. The experimental values ($a = 3.25\ \text{Å}$ and $c = 5.20\ \text{Å}$, Ref. 20) are overestimated by 1.2% and 2.0%, respectively. The ZnO thin film is modeled by a $(1 \times 2)$ seven-layer slab supercell in [1120] orientation, as shown in Fig. 1, containing 28 formula units. The top and bottom surfaces are separated from other slabs by a vacuum region of 10 Å thickness. Our supercell takes into consideration surface effects which are neglected in bulk calculations. Note that in our model, the top and bottom of the slab are equivalent by symmetry since the substitution of Zn by Sc atoms is done on both sides of the slab. The energetically preferable sites for the Sc dopant are determined by calculating the total energy of substitutional Sc in the surface and subsurface layers. The subsurface site is 0.99 eV lower in energy than the surface site.

In order to investigate the magnetic interaction and the preferred distance between two Sc atoms, we substitute two Zn atoms by Sc atoms on the top and bottom of the slab, giving rise to a doping level of 4/28 (~14%). We will study the four configurations shown in Fig. 1. To determine the magnetic state, the total energy is calculated while the spin of the two Sc atoms is set parallel or antiparallel, representing ferromagnetism (FM) or antiferromagnetism (AFM). The energy difference $\Delta E = E_{\text{AFM}} - E_{\text{FM}}$ (per Sc) indicates the magnetic ground state of the system, where positive $\Delta E$ corresponds to FM.

We start with an analysis of the magnetic coupling between a pair of Sc atoms in the configurations displayed in Fig. 1. In configuration C1, two Zn atoms are replaced by Sc at nearest-neighbor sites in the surface layer of the slab (distance 3.37 Å). In configuration C2, two Zn atoms are substituted by Sc in the surface layer at a distance of 5.7 Å. Configuration C3 is obtained by replacing two Zn atoms by Sc impurities at nearest-neighbor sites in the surface and subsurface layers (distance 3.38 Å). Finally, in configuration C4 two Zn atoms are replaced by Sc in the subsurface layer at a distance of 3.41 Å.

We find that configuration C1 shows a FM ground state (AFM state is 0.88 meV higher in energy). The Zn-O and Sc-O bond lengths are different at the surface and in the bulk. The Zn-O bond length along the [0001] and [1100] directions changes from the initial 2.01 Å and 2.00 Å, to 1.91 Å and 1.97 Å, respectively. The analogous Sc-O bond length decreases from 2.01 Å and 2.00 Å, to 1.97 Å and 1.97 Å, respectively. In contrast, the Sc$_1$-Sc$_2$ bond length increases during the relaxation from 2.21 Å to 3.37 Å. In the FM state of configuration C1, the magnetic moments are mainly localized on the surface Sc atoms, with a local magnetic moment of 0.065 $\mu_B$. The magnetic moments are almost exclusively due to the Sc 3$d$ states. In contrast, magnetic moments in bulk Sc-doped ZnO with Zn vacancies are mainly due to the 2$p$ gap states of the O atoms around the Zn vacancies. Note that the O atom in the surface layer of our slab has a very small local magnetic moment of 0.005 $\mu_B$.

In configuration C3, the FM state is 0.63 meV lower in energy than the AFM state. The Sc$_1$-Sc$_2$ distance changes from the initial 3.25 Å to 3.407 Å during the relaxation. The Sc$_1$-O and Sc$_2$-O bond lengths are 1.94 Å and 2.03 Å, in the surface and subsurface layer, respectively. The difference to configuration C1 is that the Zn atoms next to Sc atoms in the surface layer are magnetized with a moment of 0.105 $\mu_B$. We also find that the O neighbors of Sc atoms in the surface and subsurface layers show smaller magnetic moments of 0.020 $\mu_B$ and 0.018 $\mu_B$, while Sc$_1$ and Sc$_2$ carry weak moments of 0.005 $\mu_B$ and 0.001 $\mu_B$. The FM state of configuration C3 is 1.67 eV lower in energy than the FM state of configuration C1. The Sc-O distances are similar in C1 and C3, but the Sc$_1$-Sc$_2$ distances are rather different. Configurations C2 and C4 do not show any magnetization.

To check the convergence of our calculations with respect to the supercell size, we compare fully relaxed supercells with different thicknesses along the [1120] direction.

![FIG. 1. Side views of four configurations with two substitutional Sc atoms in a (1120) surface slab with seven ZnO layers. The light blue (light gray) spheres are Zn atoms, the red (gray) are O atoms, and the blue (dark gray) are Sc.](image)

![FIG. 2. Total spin-polarized DOS for configurations C1 and C3. Spin up and spin down correspond to positive and negative values, respectively. The vertical dashed line denotes the Fermi level.](image)
We address slabs of 9 layers and 11 layers with a total of 72 and 88 atoms, respectively. We find that FM is more favorable than AFM with energy differences of 0.66 meV. When the thickness increases beyond 7 layers, the magnetic moment shows no significant change. The same is observed for transition metal doping of ZnO.23–25

To elucidate the role of the Sc-doping on the electronic structure and to obtain information on the roles of the individual orbitals and atoms, we address the GGA+U density of states (DOSs). Figures 2 and 3 provide the total and partial DOSs of the FM calculations for configurations C1 and C3. They show common features: (i) The Zn states are localized between $-10$ and $-9$ eV, well below the O $2p$ states. (ii) The occupied O $2p$ states appear between $-7$ and $-3$ eV showing some hybridization with the Zn $4d$ states. (iii) Sc contributions to the valence states are small. It is interesting to note that the Sc doping maintains the semiconducting nature of ZnO and introduces impurity states at the bottom of the conduction band (both for the majority and minority spin channels). However, in the vicinity of the Fermi energy the electronic states of the two configurations show different behaviors. The DOS of C1 in Fig. 3(a) shows that the Sc $3d$ states dominate at the Fermi energy. We observe that the O $2p$ orbital is hybridized slightly with the Sc $3d$ orbital, see Fig. 3(c), and O states appear at the Fermi level. Nonetheless, only a very weak polarization affects the surface O atoms. In the case of configuration C3, see Fig. 3(d), we notice a simultaneous hybridization between the Zn $4s$, O $2p$, and Sc $3d$ states around the Fermi level.

The spin density is calculated for configurations C1 and C3, and displayed in Fig. 4 as isosurface plots.26,27 Figure 4(a) shows that the spin-polarized electrons are localized at

![Isosurface spin density plot for configurations (a) C1 and (b) C3 at an isovalue of 0.01 electron/Å³.](image)
the Sc sites in the surface layer. The spin density distribution has a d-like shape, which indicates that the polarization is induced by the d orbitals and thus confirms a local nature of the magnetic moments in the system. Turning to configuration C3 in Fig. 4(b), we find that the magnetization is carried mainly by the Zn s orbitals due to the s-like shape of the isosurface.

In summary, we have performed ab-initio calculations to investigate the electronic structure and magnetic properties of Sc-doped ZnO thin films. We conclude that even though Sc originally is not magnetic, it can induce ferromagnetism in ZnO (1120) thin films, in agreement with experiments. However, we have identified only two substitution patterns which result in spin polarization. In both cases, ferromagnetism is energetically preferred. Configuration C3 is more stable than configuration C1, in which the spin polarization is carried by the Sc 3d states (as to be expected for transition metal doped ZnO). It is found that the spin polarization in configuration C3 is connected to a strong hybridization between the Sc 3d states and the ZnO host. While so far it has been assumed that mainly the transition metal d orbitals are responsible for the magnetism in doped ZnO thin films, our results for Sc doping draw a different picture. The spin polarization affects highly delocalized hybrid states (comprising Sc d, O p, and Zn s orbitals) formed at the surface of the ZnO thin film. In a realistic experiment, the doping process should result in a random configuration of the impurities of C1 and C3 type. Note, however, that configuration C3 is most likely to occur due to its lower energy. Our study shows that the magnetism in Sc-doped ZnO probably possesses an itinerant character.

26The three-dimensional spin-density is obtained by the full-potential (linearized) augmented plane waves plus local orbitals method27 in the GGA-PBE approximation. The self-consistent procedure is carried out with $R_{MT} = 8$ and the Brillouin zone integrations are performed with the special k-points method over a $8 \times 6 \times 1$ Monkhorst-Pack mesh.19
